ABSTRACT

Arrhythmogenic right ventricular cardiomyopathy (ARVC) is a rare genetic disorder characterized by fatty degeneration of the right ventricular myocardium with variable involvement of the left ventricle. The condition is associated with exercise-mediated ventricular tachycardia and is one of the recognized causes of sudden cardiac death in the young and in athletes. Here, we report the first confirmed case of ARVC in Oman and present its electrocardiographic, echocardiographic features, and radiological findings on gated, contrast-enhanced cardiac computed tomography. Our patient was a 22-year-old male who had presented to our hospital for evaluation and investigation of syncope and symptomatic palpitations.

Arrhythmogenic right ventricular cardiomyopathy (ARVC) is a genetically mediated cardiomyopathy characterized by fibro-fatty degeneration and aneurysmal dilatation of the right ventricle (RV) myocardium with variable degrees of left ventricular (LV) involvement. The condition is transmitted as an autosomal dominant disease and predisposes to exertional ventricular tachycardia (VT).¹ There is an autosomal recessive form of the disease known as Naxos disease, which is distinguished by palmoplantar hyperkeratosis.

ARVC is a recognized cause of sudden cardiac death (SCD) in young athletes. Descriptions of the condition were reported in the Pope's Physician in 1736.² This described four generations of one family with progressive heart failure, SCD, and unusual pathologic findings on autopsy. Marcus et al,³ provided the first systematic description of 24 adults presenting with VT, all with a left bundle branch block (LBBB) morphology and superior axis. Further pathognomonic electrocardiographic features of the disease were described by Fontaine et al,⁴ who was credited with coining the electrocardiographic epsilon (σ) wave.

The diagnosis of ARVC requires the identification of major and minor criteria laid down by the working group on myocardial and pericardial diseases of the European Society of Cardiology in 1994, which was revised in 2010 [Table 1]. The diagnosis is made by the identification of two major criteria, one major

and two minor criteria, or four minor criteria.^{5,6} There is no curative therapy for the condition given its degenerative nature.

In this report, we describe a case of ARVC in a young man who was treated at a tertiary care hospital. To the best of our knowledge, this description is the first confirmed case of definite ARVC in Oman.

CASE REPORT

A 22-year-old male, who was a non-professional but avid football player was admitted to the Sultan Qaboos University Hospital twice over one month for evaluation and investigation of syncope and symptomatic palpitations. His past medical health was unremarkable, except for periods of violent palpitations experienced while playing football. Before the first hospitalization, there was a witnessed brief syncopal event (< 1 minute) with rapid recovery to baseline.

On admission, his clinical examination was unremarkable. His baseline electrocardiogram (ECG) showed precordial T-wave inversions in V₁, V₂, and V₃ but no other abnormalities. A quick bedside transthoracic echocardiogram was performed, which ruled out hypertrophic cardiomyopathy. A 24-hour Holter monitoring was undertaken during hospitalization and showed no significant arrhythmias. There was a six-second sinus pause noted during sleep. He was then subjected to an exercise stress test. He exercised for 20 minutes

<p>6. Family history</p> <ul style="list-style-type: none"> ARVC/D confirmed in a first-degree relative who meets current task force criteria. ARVC/D confirmed pathologically at autopsy or surgery in a first-degree relative. Identification of a pathogenic mutation categorized as associated or probably associated with ARVC/D in a patient under evaluation. 	<ul style="list-style-type: none"> History of ARVC/D in a first-degree relative whom it is not possible or impractical to determine whether the family member meets the current task force criteria. Premature death (< 35 years of age) due to suspected ARVC/D in a first-degree relative. ARVC/D confirmed pathologically or by current task force criteria in a second-degree relative.

Diagnosis: Definite = 2 major or 1 major + 2 minor or 4 minor; Borderline = 1 major + 1 minor or 3 minor; Possible = 1 major or 2 minor.

2D-echo: 2D-echocardiogram; PLAX: parasternal long axis; PSAX: parasternal short axis; RVOT: right ventricular outflow tract; BSA: body surface area;

MRI: magnetic resonance imaging; RV: right ventricle; ECG: electrocardiogram.

(Bruce protocol) without significant exercise-induced arrhythmias. There was an adequate heart rate response to exercise and normal recovery in the post-exercise period. He was discharged after 48-hours of observation and followed-up in

the cardiac electrophysiology clinic. Two weeks later, he was readmitted with severe symptomatic palpitations. This time, the palpitations occurred after playing football and persisted. He was presyncopal and evaluated at a local health center.

Figure 1: On presentation, a 12-lead electrocardiogram showed ventricular tachycardia of a left bundle branch morphology and superior axis.

A wide-complex tachycardia was documented, and he did not respond to a trial of intravenous adenosine up to 12 mg. His initial 12-lead ECG at the University Hospital showed ventricular tachycardia with LBBB morphology and superior axis [Figure 1]. He was cardioverted back to sinus rhythm and treated with intravenous amiodarone. His post-cardioversion ECG showed persistent T-wave inversions in leads V_1 , V_2 , and V_3 as well as epsilon waves [Figure 2]. A complete 2D-echocardiogram (2D-echo) was performed and documented a dilated, moderately hypokinetic RV with prominent trabeculations [Figure 3]. Due to unavailability of facilities for cardiac magnetic resonance imaging, a gated cardiac computed tomography (CT) was performed. This ruled out coronary anomalies and confirmed the presence of right ventricular outflow tract (RVOT) dilatation. There were hypodense lesions noted

on the RV aspect of the interventricular septum, RV trabeculae, and the RV free wall and inferior-apical RV wall [Figure 4]. The appearance and density was consistent with adipose tissue. There was also scalloping noted in the basal inferior wall. The patient was maintained on bisoprolol and intravenous amiodarone. He was transferred to the national cardiac electrophysiology center for automatic implantable cardioverter defibrillator (AICD) implantation for secondary prevention. His 10 siblings will undergo electrocardiographic and echocardiographic screening on an outpatient basis.

DISCUSSION

In this young male, the diagnosis of definite ARVC was established by satisfying multiple major criteria. These included the documentation of sustained

Figure 2: Post-electrical cardioversion 12-lead electrocardiogram showing epsilon waves (red arrows).

Figure 3: Apical four-chamber view showing a dilated right ventricle with a basal dimension of 47 mm (normal is < 43 mm) and prominent trabeculations toward the apical segments.

VT of the morphology described in Table 1 (arrhythmia criteria), the presence of epsilon waves (depolarization criteria) and T wave inversions in V_1 , V_2 , and V_3 in the absence of complete Right Bundle Branch Block (RBBB) (repolarization criteria). The imaging modalities added further insight in documenting RV structural abnormalities on 2D-echo and cardiac CT.

Due to the varied clinical manifestations of the condition, the exact prevalence is difficult to ascertain. In the SCD literature, ARVC accounts for 11–22% of cases in young athletes. The prevalence

in the general population is 1:5000 with men three times more commonly affected than women.⁷

The most common presentation is in the form of exercise-induced sustained and non-sustained VT. This classically originates from the RV and, therefore, has LBBB morphology and a superior axis. Clinically, patients present with recurrent palpitations and syncope. In advanced cases, heart failure dominates the clinical picture.⁸

Once documented, VT is treated pharmacologically with the combination of β -blockers and class III antiarrhythmic agents (amiodarone or sotalol). An AICD is indicated in patients with prior aborted SCD or documented VT (secondary prevention). The device is also indicated for primary prophylactic indications in patients with severe RV dilatation, extensive RV involvement, inducible VT at the time of electrophysiological study, and in the presence of documented spontaneous non-sustained VT on non-invasive monitoring.⁹

There has been an increasing interest in cardiac CT imaging in identifying patterns of adipose deposition characterizing the disease. Characteristic findings include thinning of the RVOT, free wall subepicardial fatty infiltration, fat in the moderator band, trabeculae, and ventricular septum.¹⁰ Some of these were seen in our patient. More recently, a CT scoring system has been devised and validated by a team of Japanese investigators with superior diagnostic and discriminatory ability. Using this

Figure 4: Axial cardiac computed tomography images at the level of the interventricular septum and base of the heart (a) showing fatty infiltration of the right ventricular side of the septum extending into the adjacent trabeculae (red arrow). (b) Fatty infiltration of the anterior and inferior wall of the right ventricle (short red arrow) and scalloping of the anterior wall (long red arrow).

system, the diagnosis of definite ARVC can be achieved with 90% accuracy.¹¹

CONCLUSION

This is the first report of a case of ARVC in Oman. Our report also describes the unique findings characterizing the disease condition on gated cardiac CT, which has been gaining increasing interest as a diagnostic technique. The condition requires a high index of suspicion as it is an important cause of SCD in the young. The genetically-mediated, progressively degenerative nature of the disease has major implications for family screening. Device therapy with AICD is a cornerstone in the management for both primary and secondary preventive indications.
